ABSTRACT

Cardiovascular magnetic resonance (CMR) has evolved from a pioneering research tool to an established noninvasive imaging method for detecting inducible myocardial perfusion deficits. In this consensus document, experts of different imaging techniques summarize the existing body of evidence regarding CMR perfusion as a viable complement to other established noninvasive tools for the assessment of perfusion and discuss the advantages and pitfalls of the technique. A rapid, standardized CMR perfusion protocol is described, which is safe, clinically feasible, and cost-effective for centers with contemporary magnetic resonance equipment. CMR perfusion can be recommended as a routine diagnostic tool to identify inducible myocardial ischemia. (J Am Coll Cardiol Img 2016;9:1338-48) © 2016 by the American College of Cardiology Foundation.

ardiovascular disease remains a leading cause of morbidity and mortality worldwide, with coronary artery disease (CAD) being the most prevalent condition. Effective diagnosis and risk assessment are essential, and the presence and extent of myocardial ischemia, scar, and viability as well as the volumes and function of the left ventricle (LV) are key parameters in guiding care.

Recent data have demonstrated that primary angiographic assessment of patients with suspected coronary artery stenosis is often insufficient for therapeutic decision making. The detection of substantial areas of inducible ischemia is increasingly mandated to justify revascularization and provide a clinical benefit (1-4).

Cardiovascular magnetic resonance (CMR) is established as a well-validated, highly standardized technique, but still remains underutilized for ischemic heart disease for a number of reasons. Among referring cardiologists and family care physicians, CMR is perceived as a highly complex research tool of limited availability, which requires specialized

training of physicians and technicians. It is considered useful mostly for providing scientific data at high costs with long scan times rather than delivering essential clinical data with acceptable effort. In some health systems, CMR is insufficiently reimbursed or difficult to access, and there are not enough adequately trained imagers.

The basis of this paper is consensus of imaging specialists with various backgrounds. Consensus was reached by: 1) a face-to-face meeting; 2) a written proposal from the core writing group (R.H., M.F., J.S.-M., C.Z., and E.N.); and 3) iterative integration of any comment from the other authors. We summarize the existing body of evidence on the diagnostic accuracy, prognostic value, and resource- and timeeffectiveness of contemporary first-pass perfusion CMR for the assessment of ischemic heart disease. We describe an efficient CMR perfusion protocol that allows guiding on subsequent patient management. Magnetic resonance (MR) coronary angiography or methods on the basis of other modalities (singlephoton emission computed tomography [SPECT], positron emission tomography [PET], computed tomography perfusion, or stress echocardiography) will not be addressed in this paper. Dobutamine stress CMR will only be included as far as some of the published data does not discriminate between the 2 methods, although it is a highly attractive alternative in patients with contraindications to vasodilator stress. This review closes a knowledge gap between the guidelines and more recent evidence provided by clinical trials, and it merges these data with the extensive clinical practice within different settings reflected by a group of imaging specialists.

CMR IN CURRENT GUIDELINES

Current guidelines may not fully reflect the most recent scientific evidence on CMR due to new evidence that has been obtained since their publication.

In general, all recent guidelines provide a Class I or IIa recommendation for the use of ischemia imaging before invasive angiography in symptomatic patients with an intermediate pre-test likelihood between 15% and 85% (5-9). The choice of imaging modality (SPECT, CMR, echocardiography, or PET) is usually left to local conditions, physician or patient preference, and specific considerations.

The latest American College of Cardiology Foundation appropriate use criteria consider CMR appropriate for a large number of indications, including the diagnosis of ischemic heart disease with

increasing strength at higher individual risk profiles (Table 1) (10).

CMR PERFUSION

SUMMARY OF CURRENT SCIENTIFIC EVIDENCE.

The evidence for the utility of perfusion CMR is considerable, including validation studies in animals against microspheres (11-13), single-center studies in selected patient populations, examination of interstudy reproducibility (14,15), and large, prospective

randomized trials (16,17). CMR combines a number of favorable characteristics: 1) very good spatial resolution, allowing for the assessment of subendocardial ischemia; 2) robust image quality, independent of body habitus; 3) good temporal resolution, allowing the wash-in of the contrast agent to be visualized; 4) complementary information on LV volume, function, and morphology; and 5) tissue characterization (e.g., myocardial edema, scar, and infiltration). Additionally, CMR is not associated with ionizing radiation and possesses few contraindications and limitations, such as severe arrhythmia, severe or acute renal dysfunction, or incompatible devices (Table 2).

Table 3 provides a summary of the evidence from 6 large meta-analyses comparing first-pass perfusion CMR against invasive angiography. Jaarsma et al. (18) compared perfusion CMR, SPECT, and PET and found similar accuracies for CMR and PET, which were both superior to SPECT (Figure 1). de Jong et al. (19) compared first-pass perfusion CMR, SPECT, and stress echocardiography and found a superior accuracy of perfusion CMR versus both latter methods, which did not differ. More recently, 2 meta-analyses of noninvasive imaging versus invasive hemodynamics (fractional flow reserve) were published (20,21), and similarly demonstrated better diagnostic performance of perfusion CMR and PET versus SPECT and perfusion computed tomography (Figure 2).

The 2 largest studies comparing the accuracy of CMR and SPECT for the detection of CAD are MR-IMPACT II (Magnetic Resonance Imaging for Myocardial Perfusion Assessment in Coronary artery disease Trial II) (17) and CE-MARC (Clinical Evaluation of Magnetic Resonance Imaging in Coronary Heart Disease 2) (16,22). In both studies, patients were assessed with CMR, SPECT, and invasive angiography. The MR-IMPACT II trial (17) recruited 533 patients in 33 European and U.S. centers using coronary angiography as the standard of reference. Using a predefined criterion for positivity of 1 segment with "black or dark gray" appearance and neglecting all

clinical data as well as CMR information on the basis of late gadolinium enhancement, the sensitivity of first-pass perfusion CMR to detect coronary artery stenosis was superior (0.67 vs. 0.59), whereas specificity was inferior to SPECT (0.61 vs. 0.72). The primary endpoint of the study was reached, demonstrating noninferiority of CMR versus SPECT

TABLE 2 Advantages and Limitations of CMR and SPECT for Perfusion Imaging					
	CMR	SPECT			
Ionizing radiation	None	Yes (1-15 mSv)			
Image resolution	${<}3\times3\times8$ mm, cardiac coverage in 3–5 imaging planes	App 8 \times 8 \times 8 mm, full 3D cardiac coverage			
Full LV coverage	Only with 3D	Yes			
Underlying mechanism	First-pass flow of contrast agent	Cellular isotope uptake			
Renal dysfunction	Not performed in patients with eGFR <30 ml/min/1.73 m ² due to presence of a low risk of NSF Contrast agents are not nephrotoxic	No limitation			
Arrhythmia	Image quality can be reduced in absolute arrhythmia or frequent PVCs (>10/min)	No limitation			
Devices	Contraindicated with devices such as most ICDs and pacemakers	No limitation			
Validation	Excellent validation against invasive angiography, FFR, and outcome	Excellent validation against invasive angiography, FFR, and outcome			
Availability	Limited to state-of-the art centers	Widely available			
Costs	Variable. In most countries relatively high	Variable. In most countries medium to high			
Patient characteristics	Scanners with larger bores available for severe obesity or unfavorable body habitus	Increased risk of artifacts with obesity, risk of "balanced ischemia" in triple-vessel disease			
3D = 3-dimensional; CMR = cardiac magnetic resonance; eGFR = estimated glomerular filtration rate; FFR = fractional flow reserve; ICD = implantable cardioverter-defibrillator; LV = left ventricular; NSF = nephrotic systemic fibrosis: PVC = premature ventricular complex: SPECT = single-photon emission computed					

tomography.

(17). The specificity of CMR perfusion was somewhat lower than in previous publications. This was partially due to: 1) a pre-defined cutoff value, which may not have been optimal for all sequences and vendors; 2) using the "lowest common denominator" for the CMR techniques on various systems; and 3) the blinded readers having variable experience with sequences not used in their own institution. An important message to be drawn from this study is the need for on-site training using a standardized approach. The CE-MARC study (16) recruited 752 patients in a single center and found higher sensitivity, higher positive and negative predictive values, as well as better overall diagnostic accuracy of CMR when compared with SPECT. Specificity was similar for the 2 tests. In both studies, receiver-operating characteristic curve analyses showed higher values for CMR in comparison with SPECT for subgroups, such as in triple-vessel disease or in women (23).

The recently presented CE-MARC II study demonstrated, in 1,202 patients with stable angina and a broad range of pre-test likelihoods, that ischemia testing with CMR perfusion imaging or SPECT imaging led to a significantly lower number of negative invasive angiographies compared with the U.K. National Institute of Clinical Excellence (NICE) guidelines, which recommend management on the basis of pre-test likelihoods (pre-test likelihood 10% to 29%: calcium-scoring; 30% to 60%: noninvasive testing; and >60%: invasive coronary angiography). Importantly, outcome (major adverse cardiovascular events) after 1 year was similar in the 3 groups (24). Further evidence is expected in the near future from another large-scale multicenter trial, which has finished recruitment and is awaiting patient outcome data (25).

PROGNOSTIC VALUE OF CMR. Several studies on vasodilator or dobutamine stress CMR have demonstrated an excellent prognostic value (26-31). The 5-year follow-up of the CE-MARC study showed that CMR, but not SPECT, added to risk stratification of patients with suspected CAD beyond classic risk factors (32). A recent meta-analysis of 19 studies (14 with vasodilatory agents, 4 with dobutamine, and 1 combined) found a higher incidence of myocardial infarction (odds ratio [OR]: 7.7), cardiovascular death (OR: 7.0), and both endpoints combined (OR: 6.5) for an abnormal stress test during a mean follow-up of 32 months. The combined outcome (annualized event) rates were 4.9% for an abnormal versus 0.8% for normal stress CMR (Figure 3) (33). A similar prognostic value has been demonstrated in patients with known CAD (34). More recently, Heydari et al. (35) have shown the value of vasodilatory stress perfusion CMR for risk stratification and patients with diabetes and found a yearly event rate of 0.5% for cardiac death or myocardial infarction in patients without scar or inducible ischemia, whereas those with inducible ischemia had an event rate of 8.2% (35). In addition, there are strong data on scar imaging using late gadolinium enhancement as an independent and additional marker for outcome. This is of specific importance as ischemic scars can be found in 17% (95% confidence interval: 14% to 19%) of older patients without other signs on previous myocardial infarction in their history, echocardiogram, or electrocardiogram (36).

SAFETY OF CMR. Large registry studies in well over 30,000 patients worldwide have demonstrated the excellent safety of the CMR procedure. The EuroCMR registry enrolled more than 27,000 consecutive patients. Mild complications were detected in 994 patients (3.6%), with most events (e.g., dyspnea, chest pain, extra systoles, and so on) occurring during dobutamine or adenosine infusion. Only a total of 7 (0.026%) severe complications were encountered (2 nonsustained ventricular tachycardia and 1 ventricular fibrillation during dobutamine infusion, 2 overt heart failures, 1 unstable angina, and 1 anaphylactic shock in the setting of adenosine stress) with no deaths reported. Procedural safety was not dependent on age or sex of the patient, or on the country or center where the scan had been performed (37). A retrospective analysis of 5,782 consecutive Canadian CMR patients recorded moderate to severe complications after contrast agent administration in 9 (0.16%) contrast-enhanced studies, characterized by nausea and vomiting in 6 (0.12%) and by symptoms of an acute systemic allergic reaction in 2 (0.04%). None of the patients required hospitalization. Transient, asymptomatic atrioventricular block was not systematically recorded, but was observed in 5% of adenosine scans (38).

A study looking specifically at the safety of contrast agents found that the gadolinium chelate contrast agents are generally well-tolerated, with rare allergic reactions (0.12%) (39). In addition, gadolinium chelates cause no kidney damage at commonly used doses. However, the occurrence of nephrotic systemic fibrosis, a debilitating disease due to irreversible fibrosis of various tissues, after application of high doses of gadolinium-containing contrast agents in patients with reduced renal function have led to a more careful application of these agents. Health authorities (U.S. Food and Drug Administration and European Medicines Agency) classify contrast agents as high-risk (gadoversetamide, OptiMARK

macrocyclic agents (Dotarem, Guerbet; or Gadavist, Bayer) is recommended in patients with reduced kidney function (estimated glomerular filtration rate <60 ml/min/1.73 m²).

More recently, brain deposits of gadolinium in the basal ganglia have been observed after repeated (\geq 4) high-dose injections of gadolinium-containing contrast agents. Although this has not been linked to any harm or adverse health effects, it further supports the use of low doses of the most stable contrast agents (40). We also recommend the use of low doses for standard use (41).

Although mechanical valves pose no risk for a CMR examination, devices such as implantable cardioverter-defibrillators, cardiac resynchronization therapy, or pacemakers are still widely considered to be contraindicated. However, even in patients who underwent MR scans with such devices, complications have been very rare, and MR-safe devices are now available (42,43).

It is important to re-emphasize that CMR does not use any ionizing radiation or radioactive material, which may be preferable especially in young and in female patients.

COST-EFFECTIVENESS OF CMR. Cost effectiveness data vary enormously among various cost structures as well as various patient populations (44). In general, a higher pre-test likelihood (e.g., >83%) for the presence of significant CAD warrants the use of invasive coronary angiography (ICA) as the first test, whereas lower pre-test likelihoods are in favor of

Annualized event rates are shown for (A) cardiovascular death, (B) all-cause mortality, and (C) nonfatal MI in abnormal and normal perfusion CMR, and for (D) positive and negative LGE. CAD = coronary artery disease; CMR = cardiac magnetic resonance; LGE = late gadolinium enhancement; MI = myocardial infarction.

noninvasive strategies. No explicit data are available for cost-effectiveness calculation of patient populations with low to intermediate pre-test likelihoods using CMR. However, data from intermediate to high pre-test likelihood groups support the use of CMR as a first line technique.

The European CMR registry compared the costs of a "CMR first" strategy (assessment of myocardial ischemia by CMR, followed by ICA as second step if the index CMR was positive) with an "ICA only" strategy (45). In the public sectors of the German, United Kingdom, and Swiss health care systems, cost savings from a CMR-first-driven strategy were 50%, 25%, and 23%, respectively, versus outpatient ICA. If ICA was carried out as an inpatient procedure, cost savings were 46%, 50%, and 48%, respectively. In the United States, costs were reduced by 51% when compared with inpatient ICA, but increased by 8% for CMR versus outpatient ICA (45). More recently, a calculation for "CMR first" versus ICA supported by fractional flow reserve demonstrated superior cost effectiveness for the CMR-driven strategy in groups with 62% to 83% CAD prevalence (depending on the country, highest for the United States) and equality in groups with a prevalence >83% (46).

A cost-effectiveness analysis of the CE-MARC study used a decision analytic model to compare 8 strategies for the diagnosis of CAD in outpatients referred to cardiologists for further evaluation of angina pectoris (47). Different combinations of

ED = end-diastolic; ES = end-systolic; Gd = gadolinium; IV = intravenous; LAX = long-axis view; LV = left ventricular; SAX = short-axis view; other abbreviations as in Figure 3.

exercise treadmill testing, SPECT, CMR, and ICA were considered. Only 2 strategies were costeffective for the diagnosis of CAD: 1) exercise treadmill testing followed by CMR if positive or inconclusive, followed by ICA if abnormal or inconclusive; and 2) CMR followed by ICA if inconclusive. The use of SPECT was not cost-effective in this single-center study.

CMR PROCEDURES IN ISCHEMIC HEART DISEASE

PERFUSION CMR. Perfusion CMR is usually performed during pharmacological vasodilation with agents such as dipyridamole, adenosine, and, more recently, regadenoson (48). When administered intravenously, the subsequent vasodilation increases coronary blood flow approximately 2- to 4-fold. This results in visible differences between the blood flow in myocardium subtended by normal coronary arteries as opposed to coronary arteries with significant stenosis. CMR uses an intravenous bolus of an MR contrast agent, typically 0.05 to 0.1 mmol/kg body weight of a gadolinium-based agent, for detecting these flow differences. Signal intensity is related to contrast concentration, and analysis can be performed in a quantitative, semiquantitative, or qualitative fashion (49,50). Current recommendations from the Society for Cardiovascular Magnetic Resonance recommend a qualitative assessment in clinical routine, identifying visually apparent delays and reductions of contrast inflow (51). Larger defects are prognostically more important (52). Semiquantitative analysis of the upslope of the input functions is possible and also provides clinically useful information regarding microvascular function (53).

Full quantification of CMR perfusion is becoming possible (11,54,55) but requires certain technical approaches exceeding usual routine scanning, which are not discussed in the current paper. It is of interest to note, though, that quantification of myocardial perfusion reserve for the assessment of microvascular dysfunction is increasingly demonstrating clinically important findings (56).

LATE GADOLINIUM ENHANCEMENT. In clinical practice, almost every CMR first-pass perfusion scan is followed by contrast-enhanced CMR images, typically performed 10 to 15 min after contrast injection (late gadolinium enhancement). The first pass of the contrast agent through the myocardium is used for perfusion imaging. The contrast agent then diffuses freely into the interstitial space (but remains outside of the cells), which allows demarcating areas where interstitial space is increased (e.g., scar tissue after myocardial infarction).

Scar imaging has become a standard procedure as a robust, well-validated, and accurate tool for the detection of myocardial necrosis. Even though the enhanced signal is not specific for an ischemic etiology of a scar, the regional distribution patterns of abnormal areas allow differentiation of ischemic from nonischemic injury. Ischemic scars involve the subendocardial layer and usually follow the territories defined by coronary anatomy. Scars due to myocarditis or cardiomyopathy show a distinctly different distribution pattern. Validation in animals and clinical studies demonstrate a significantly higher detection rate of subendocardial scar by CMR in comparison to SPECT imaging due to the higher spatial resolution (36).

CINE CMR IMAGING OF LV FUNCTION. Electrocardiogram-gated dynamic cine CMR sequences provide a noninvasive, accurate, and reproducible measurement of ventricular volumes, function, and regional wall motion. The heart is typically covered by a series of short- and long-axis views for volumetric and functional ventricular analysis. This may either comprise a complete short-axis stack with additional long-axis views or a combination of short- and longaxis views. Data on LV morphology, mass, volumes, and function can be acquired in 2 breath-holds (51), and modern approaches to data compression (e.g., compressed sensing) make real-time or single breathhold 3-dimensional acquisitions a reality (57). Enddiastolic or -systolic volumes, stroke volume, ejection fraction, and myocardial mass can be determined with high accuracy (58,59). Advantageous for cine CMR is the independence for any imaging windows as well as the excellent contrast between blood and myocardium for all segments, leading to excellent precision for the assessment of volumes and mass (60).

RECOMMENDED CMR PROTOCOL FOR CAD

Advances in CMR technology permit standardized short and simple protocols, resulting in timeefficient, user- and patient-friendly examinations. The protocol for the assessment of ischemic heart disease with vasodilator stress was discussed and agreed between all authors as a consensus and can be adapted for specific local environments or circumstances. It is used routinely in most of the centers of the writing group, but has only partially been scientifically explored. Further studies are required to systematically assess its value and potential for further improvement. The proposed protocol may be performed in a single 25- to 30-min session (Central Illustration). Dependent on local preferences, various stress agents (adenosine, dipyridamole, or regadenoson) may be used. Adenosine has a short half-life of <10 s and requires continuous infusion during the imaging procedure. The advantages of the short half-life are the brief duration of potential side effects as well as the possibility to measure function and rest perfusion soon after the stress scan, as the hemodynamic effects are rapidly reversed. Dipyridamole is less frequently used, due to its longer half-life and less reproducible vasodilation, with subsequent inferior results. Regadenoson is increasingly applied due to a longer half-life and the resulting ease of use (bolus administration, single non-weight-based dose). Regadenoson is administered intravenously 1 min before contrast injection reducing the need for infusion pumps and 2 intravenous lines. The disadvantages of the longer halflives of dipyridamole and regadenoson are the longer persistence of side effects and the difficulty to obtain a true resting function and perfusion scan within a rapid protocol. However, with today's robust image quality and decreasing rates of artefacts, a resting perfusion scan is only required in rare cases with uncertainty about the relevance of an abnormal stress perfusion result. If required for quantification or research, the rest scan can be

performed before the stress scan. In this protocol the vasodilatory effects of the regadenoson can be reversed (e.g., with aminophylline), or the examination time can be prolonged to allow the stress to wean off. A physician must be available to read the stress images prior to the patient leaving the department. It should be noted that the use of all vasodilators (dipyridamole, adenosine, and regadenoson) for CMR perfusion imaging currently constitutes an off-label usage.

SUMMARY

During the last decade, CMR perfusion imaging has moved from an innovative research tool to widespread clinical applicability. However, the adoption of this technique has been largely limited to major centers, although an excellent safety profile and high diagnostic and prognostic value has been well demonstrated. CMR provides outstanding characterization of scar and ischemia, and improvements in hardware and software now enable this method to be performed in a timely and cost-efficient manner. The development of a focused, standardized protocol permits a rapid learning curve and patient-friendly examination using current scanners. Optimization of standardized CMR protocols now places this method as a potential first-line modality for the assessment of known or suspected ischemic heart disease.
